

And in fact Libet carried out further experiments which he took to show that this is indeed possible.

In these experiments, subjects were instructed to do two things. (1) Prepare to flex at a specific **target time** — say, when the dot is at “30.” (2) Do not flex at that time.

In these experiments, Libet observed higher EEG readings — and thus readiness potential to flex — about a second before the target time. These EEG readings were remarkably similar to those at about -500ms in the original study.

However, the EEG readings decreased around 200ms before the target time — not far off of the W time from the previous experiment.

Libet took this to mean that the subjects in the “veto” experiment decided to flex at the target time, but were able to exercise conscious free will to veto this decision about 200ms before the action.

replies to
Libet

A solid red circle with a subtle drop shadow, centered on a white background. Inside the circle, the text "the Libet experiments" is written in a white, sans-serif font, centered both horizontally and vertically.
